Abstract

Our study analyzed the performance and energy consumption of multicore applications, using a number of techniques to manage concurrent execution. We concluded that language constructs for concurrent execution can impact energy consumption. Nonetheless, the tradeoff between performance and energy consumption in multicore applications is not as obvious as it seems.

Categories and Subject Descriptors D.1.3 [Programming Techniques]: Concurrent Programming, Parallel Programming

Keywords Energy-Efficiency, Language Constructs, Concurrent Execution

1. Introduction

Measuring the energy consumption of an application and understanding where the energy usage lies provides new opportunities for energy savings. In order to understand the complexities of this approach, we specifically look at multithreaded applications. The performance of the existing constructs for concurrent execution is reasonably well-understood [3, 5]. Furthermore, since parallel programming enables programmers to run their applications faster, a common belief is that this application will also consume less energy [2]. We call this as the “Race to idle” philosophy. In summary: faster programs will theoretically consume less energy because they will have the machine idle fast.

This paper presents an empirical study consisting of the evaluation of the performance and energy consumption of four applications that use three concurrent constructs plus a sequential implementation with the goal of demonstrating that it is hard to trace tradeoffs between energy-efficiency and performance. By an evaluation of these applications in multiple environments, we show how basic parameters, such as clock frequency, threading options, and different VMs can impact energy consumption. Our study highlights the non-obvious and context-dependent nature of tradeoffs between performance and energy consumption.

2. Study Setting

To achieve the goal of this study, we ran a set of benchmark applications from different domains in a number of different configurations while varying a group of attributes. We can divide these attributes in two groups: internal (programming language construct, number of threads in use and resource usage - CPU and/or IO) and external (the clock frequency and the JVM implementation). We then provide a set of variant implementations for each benchmark using four concurrent constructs, plus a sequential implementation.

In this experiment, we used commodity hardware: an Intel(R) Xeon(R), 2.13 GHz, 4 cores/8 threads and with 16Gb of memory, running Linux 64-bit, kernel 3.0.0.-31-server. These experiments were run using three JVM: i) OpenJDK version 1.7.0_09, ii) HotSpot JDK version 1.7, and iii) JRockit version 1.6. When the experiments were performed using JRockit, we provided an external jar file containing the ForkJoin implementation.

Our experiments consisted of running these four applications in each of the three JVM implementations, scaling the CPU frequency, and limiting the number of threads in use. We ran each experiment twelve times for each workload, while measuring the system using the powertop utility. We discarded the executions with the lowest and the highest to reduce bias caused by outliers. Therefore, we have two main metrics that evaluate the experiments: the energy consumed (in Joules) and the execution time (in seconds).

3. Study Results

Table 1 shows the overall view of our experimental results. The column named “Energy Consumption (J)” organizes the results of the 10 executions. The value contained in each cell represents the median of the 10 executions, where each sample represents the total of energy consumed in this given execution. We use boldface to highlight the best result for the given benchmark application. The column “Time (s)” works similarly.

As Table 1 shows, we can notice that the results of the concurrent constructs can have significant differences. For instance, the Thread results are always more inefficient in terms of both consumption and performance, when compared to Executors. Thus, since the usage of Thread and the Executors is very similar, with a little effort, a programmer could use Executors. Table 1 also shows that the same technique can have different impact on the energy consumed. If we take into consideration the ForkJoin variant, we have, for the N-Queens and Knucleotide benchmark applications, a highly efficient trend for both performance and energy. On the other hand, considering the LargestImage application, we notice that the same ForkJoin variant consumed more energy than

ForkJoin thread creation led to an increase in energy consumption. But, input data (in case, the NxN size of the matrix). In this experiments, performance. This benchmark’s result can vary according to the behavior of the variants, e.g. the fastest and slowest variants in one JVM were the fastest and lowest variants for all of them. Although the different JVMs did affect execution time and energy consumption, similarly exhibited the worst results among the JVMs. Although the different clock frequencies, they did not significantly change the energy efficiency of applications [1, 4]. Gautham et al. [1] explore the following synchronization techniques to find an ideal solution for synchronization intensive workloads: i) spin lock ii) mutexes iii) software transactional memory. They show that Software Transactional Memory (STM) systems can perform better than locks for workloads where a significant portion of the execution time is spent in the critical sections. Trefethen [4] studies the behaviour of the NAS Benchmark suite for its energy and runtime performance. The benchmark suite considered includes I/O and compute-intensive applications. The authors concluded that there is a clear interaction between execution time and energy but this is not a simple relationship and can be affected by the computer environment and algorithmic approach used in the application. Nonetheless, none of these papers compare the energy-efficiency between techniques to manage concurrent execution.

4. Related Work

To the best of our knowledge, only two studies have dealt with the topic of understanding the impact of concurrent constructs on the energy efficiency of applications [1, 4]. Gautham et al. [1] explore the following synchronization techniques to find an ideal solution for synchronization intensive workloads: i) spin lock ii) mutexes iii) software transactional memory. They show that Software Transactional Memory (STM) systems can perform better than locks for workloads where a significant portion of the execution time is spent in the critical sections. Trefethen [4] studies the behaviour of the NAS Benchmark suite for its energy and runtime performance. The benchmark suite considered includes I/O and compute-intensive applications. The authors concluded that there is a clear interaction between execution time and energy but this is not a simple relationship and can be affected by the computer environment and algorithmic approach used in the application. Nonetheless, none of these papers compare the energy-efficiency between techniques to manage concurrent execution.

5. Conclusion

This paper presented an empirical study targeting four benchmark applications using a number of concurrent programming constructs with the goal of finding interesting tradeoffs between energy-efficiency and performance. Our approach indicates that it is possible to switch from one technique to another in order to consume less energy. Nonetheless, we also conclude that it is very hard to identify which technique is the better for a given scenario. Moreover, our experiments show that factors such as the nature of the problem to be solved, the technique used to manage concurrent execution, the CPU clock frequency, and the JVM implementation can create variations. These results lead us to conclude that it is very difficult to generalize a relationship between performance and energy consumption for concurrent systems. For these systems, winning the race to idle does not imply more energy efficiency. In the future, we intend to address this problem by conducting a broader-scoped study. The results of this new study will provide input for us to derive a catalog of energy code smell for concurrent software. Then we plan to proceed with the design of refactoring catalog that will enable application programmer to safely restructure their applications to use less energy.
